Supporting Information

ABSTRACT: The redox properties of cyclobis(paraquat-*p*-phenylene)cyclophane (CBPQT⁴⁺) render it a uniquely variable source of recognition in the context of mechanically interlocked molecules, through aromatic donor–acceptor interactions in its fully oxidized state (CBPQT⁴⁺) and radical-pairing interactions in its partially reduced state (CBPQT^{2(•+)}). Although it is expected that the fully reduced neutral state (CBPQT⁽⁰⁾) might behave as a π -donating recognition unit, resulting in a dramatic change in its binding properties when compared with the other two redox states, its role in rotaxanes has not yet been investigated. To address this challenge, we report herein the synthesis of a tri-stable [2]rotaxane in which a CBPQT⁴⁺ ring is mechanically interlocked with a dumbbell component containing five recognition sites—(i) a bipyridinium radical cation (BIPY^(•+)) located centrally along the axis of the dumbbell, straddled by (ii) two tetrafluorophenylene units linked to (iii) two triazole rings. In addition to the selective recognition between (iv) the CBPQT⁴⁺ ring and the triazole units, and (v) the CBPQT^{2(•+)} ring and the reduced BIPY^(•+) unit in the dumbbell component, investigations in solution have now confirmed the presence of additional non-covalent bonding interactions between the CBPQT⁽⁰⁾ ring, acting as a donor in its neutral state, and the two tetrafluorophenylene acceptors in the dumbbell component. The unveiling of this piece of molecular recognition in a [2]rotaxane is reminiscent of the existence in much simpler, covalently linked, organic molecules of neighboring group participation (anchimeric assistance giving way to transannular interactions) in small-, medium-, and large-membered rings.

INTRODUCTION

The neighboring group effect,^{1,2} alias anchimeric assistance, occupies a special place in the annals of physical organic chemistry and organic stereochemistry. The intramolecular nature of the effect not only leads to the speeding up of reactions^{3–8} when they are potentially operative, but also often dictates^{9–11} regio- and stereospecifically the constitutions and configurations of the products obtained under tight stereochemical control in what are geometrically constrained environments. This intramolecular effect, which was explored in acyclic as well as cyclic molecules, is one of the keystones of what became known as conformational analysis.¹² Already back in 2012, we argued in a review¹³ that the thermodynamic parameters associated with model host–guest complexes provide a good starting point to rationalize the ratio of ground-state and metastable co-conformations in bi-stable [2]rotaxanes at equilibrium. We demonstrated that these

[2]rotaxanes exhibit a strong correlation between their ground-state distribution constants and the relative free energies of closely related model complexes. We pointed out in the review that the semiquantitative treatment of the ground-state distribution of co-conformations (translational isomers)¹⁴ is reminiscent of the type of conformational analysis¹² that can be carried out on multiply substituted cyclohexane rings once the conformational free energies—also referred to as *A*-values¹²—between equatorial and axial substituents on mono-substituted cyclohexane rings are known. Although caution has to be exercised in applying the principle¹² of the additivity of *A*-values, the approach is generally one that can be used in a predictive manner. Now, let us assume that we introduce into a rotaxane a recognition site between the ring and dumbbell

components that is known to be an extremely weak one, at least in the context of a host–guest complex.¹⁵ Will we witness an intramolecular neighboring component effect in the rotaxane that is analogous to the neighboring group effect in molecules that only contain covalent bonds?

Recently, we reported¹⁶ that, although a 1:1 inclusion complex between the fully reduced π -electron-rich cyclobis-(paraquat-*p*-phenylene) (CBPQT⁽⁰⁾) ring and the π -electron-deficient guest 1,4-dicyanobenzene (DCB) can be isolated as a solid-state superstructure, the binding constant for this host–guest complex in (toluene) solution is too small to be measured by the usual techniques. Now, what if this 1:1 host–guest complex were to be transplanted, so to speak, into a rotaxane—would the DCB unit constitute a recognition site for the CBPQT⁽⁰⁾ ring? In this paper, we set out to answer this question by designing a tri-stable [2]rotaxane, which (i) allows us to explore the interactions of the CBPQT⁽⁰⁾ ring with recognition sites that reflects the electronic properties of DCB and, at the same time, (ii) makes it possible for us to understand more about the CBPQT ring in its different redox states, i.e., CBPQT⁽⁰⁾, CBPQT^{2(•+)}, and CBPQT⁴⁺ interacting with three different recognition sites on the dumbbell component—namely, π -electron-deficient, radical, and π -electron-rich sites, respectively—which have been chosen for incorporation into the dumbbell component of a tri-stable

[2]rotaxane. A bipyridinium (BIPY²⁺) unit was introduced into the dumbbell as the radical recognition site thanks to the well-established^{17–20} recognition between the CBPQT^{2(•+)} ring and the bipyridinium radical cation (BIPY^{•+}). By contrast, the choice of the π -electron-rich recognition sites for CBPQT⁴⁺ is subtle, since the ideal candidate should be able to interact with the CBPQT⁴⁺ ring, while not competing with the tendency of the π -electron-rich CBPQT⁽⁰⁾ to interact with the π -electron-deficient recognition sites on the dumbbell component. In order to meet these two requirements, we have introduced triazole units which act (i) as the π -electron-rich recognition sites for CBPQT⁴⁺ and, at the same time, (ii) as the means of templating the synthesis of the tri-stable [2]rotaxane by the copper(I)-catalyzed azide–alkyne cycloaddition²¹ (CuAAC). Finally, for the π -electron-deficient sites, tetrafluorinated phenylene (Ar^F) units are introduced¹⁶ in the knowledge that the changes in the chemical environments of these Ar^F units can be monitored by ¹⁹F NMR spectroscopy, an additional tool which would provide us with clear-cut evidence for the location of the ring component in both the fully oxidized and neutral states. Based on these considerations, we report (Scheme 1a) herein a tri-stable [2]rotaxane, where the CBPQT⁴⁺ ring is mechanically interlocked with a dumbbell component containing BIPY²⁺, triazole, and Ar^F units. By performing experiments at different redox potentials on this

[2]rotaxane, any interactions between the CBPQT⁽⁰⁾ ring and the π -electron-deficient Ar^F units in solution will be revealed. We show, by (i) ¹H and ¹⁹F NMR spectroscopies, (ii) UV/vis/NIR spectroscopy, (iii) cyclic voltammetry (CV) studies, and (iv) density functional theory (DFT)-based calculations that the different redox states of the ring interact with different recognition sites on the dumbbell component, demonstrating that this tri-stable [2]rotaxane can serve as a multi-state molecular switch.²²

RESULTS AND DISCUSSION

Synthetic Protocols. The *para*-substituted tetrafluorophenylene building block **3**, which was prepared according to literature procedures,²³ was subjected (Scheme 1b) to bromination, nucleophilic substitution with 4,4'-bipyridine, and counterion exchange (NH₄PF₆/H₂O) in order to afford the viologen-based precursor **5**·2PF₆ in an overall yield of 60%. While the radical and the π -electron-deficient sites are already incorporated into **5**²⁺, the formation of the triazole unit was achieved along with the formation of the [2]rotaxane, **1**·6PF₆, in the presence of the CBPQT⁴⁺ ring and the alkyne-functionalized stopper (STP) precursor **6**, by employing (Scheme 1b) a Cu-mediated synthetic methodology in a threading-followed-by-stoppering protocol developed recently by us.²¹ Briefly, the azide-functionalized dumbbell precursor **5**·2PF₆ and CBPQT·4PF₆ were dissolved in MeCN in a 1:1 molar ratio under an atmosphere of Ar, followed by the addition of an excess of Cu⁰ dust (diam < 425 μ m). Upon stirring of the reaction mixture for 20 min, the BIPY²⁺ units in both **5**²⁺ and CBPQT⁴⁺ are reduced by Cu⁰ to their corresponding radical cationic states, and the solution turns dark purple on account of the formation of the inclusion complex **5**^{•+}·CBPQT^{2(•+)}. Cu^I ions are generated *in situ* during this process, allowing the CuAAC reaction to take place and generate the [2]rotaxane following the addition of the alkyne-functionalized stopper precursor **6** to the reaction mixture. The dumbbell **2**·2PF₆ was also prepared (Scheme 1b) in order to serve as a reference. Compounds **1**·6PF₆ and **2**·2PF₆ were purified by column chromatography and counterion exchange (NH₄PF₆/H₂O). Characterization of the compounds was carried out by high-resolution electrospray ionization mass spectrometry (HR-ESI-MS) and by both ¹H and ¹³C NMR spectroscopies. See the Supporting Information for detailed synthetic procedures and characterizations.

Fully Oxidized States. With both the dumbbell and the [2]rotaxane in hand, we investigated their properties in their fully oxidized states by performing ¹H and ¹H–¹H COSY NMR experiments. In comparison (Figure 1b) with the ¹H NMR spectrum of the structurally symmetric **2**·2PF₆, that of **1**·6PF₆ displays a more complicated spectrum (Figure 1b) as a consequence of the presence of the ring component shuttling along the dumbbell component slowly on the ¹H NMR time scale. Since the CBPQT⁴⁺ ring is located (Figure 1a) on one portion (*vide infra*) of the dumbbell component, it has little effect on the chemical shift of one set of protons, e.g., protons **a** and **b**, etc. As a result, these protons have chemical shifts similar to those observed in the case of the dumbbell **2**·2PF₆. On the other hand, their counterparts, such as protons **a'**, **b'**, and **c'**, experience significant changes in chemical shift on account of their being much closer to the ring component. These chemical shifts define the location of the CBPQT⁴⁺ ring. Indeed, among all these shifts, that of the triazole proton (**H**_{TR}) experiences the most significant changes (Figure 1b) in

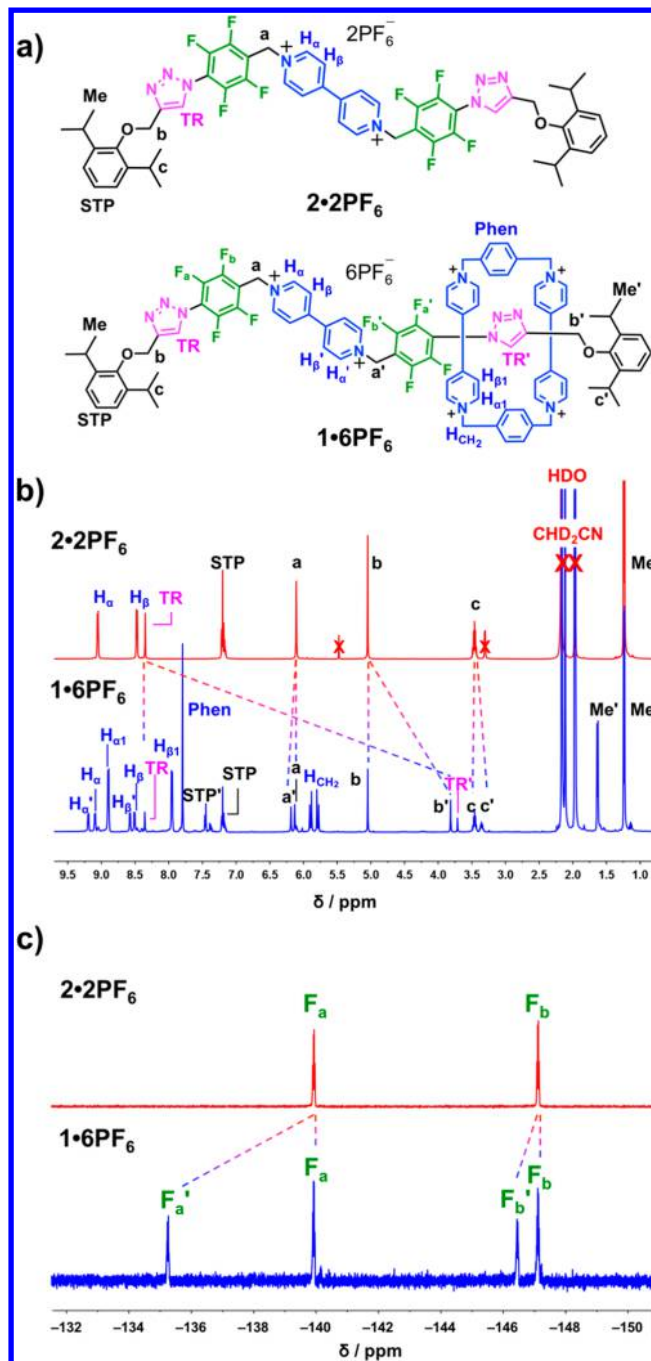

Figure 1. (a) Structural formulas of the dumbbell **2**·2PF₆ and the [2]rotaxane **1**·6PF₆, with the protons and fluorine atoms labeled. (b) ¹H NMR (500 MHz, CD₃CN, 298 K) spectra of **2**·2PF₆ and **1**·6PF₆. (c) ¹⁹F NMR (470 MHz, CD₃CN, 298 K) spectra of **1**·6PF₆ and **2**·2PF₆. The dashed lines are used to compare the chemical shifts of the signals for the dumbbell **2**·2PF₆ with those for the [2]rotaxane **1**·6PF₆.

an upfield direction by almost 5 ppm, i.e., from 8.36 to 3.72 ppm, compared with its counterpart (**H**_{TR}). This observation suggests that the shielding region of the CBPQT⁴⁺ ring, located inside the ring cavity as a result of aromatic ring currents,²⁴ has a profound influence upon one of the two triazole protons. By contrast, the signals for both protons **a'** and **H**_{a'} are shifted downfield. In addition, the ¹⁹F NMR spectrum of **1**·6PF₆ reveals that the signals for **F**_{a'} and **F**_{b'} are also downfield-shifted, compared with those of **F**_a and **F**_b,

respectively. This observation confirms unambiguously the hypothesis that, in the fully oxidized state, the CBPQT⁴⁺ ring encircles preferentially the relatively π -electron-rich triazole unit rather than the π -electron-deficient Ar^F units. It is also noteworthy that, while the shuttling motion of the CBPQT⁴⁺ ring along the dumbbell component is often observed²⁴ in analogous viologen-based [2]rotaxanes, variable-temperature (VT) ¹H and ¹⁹F NMR spectra of 1·6PF₆ show that the two sets of the peaks for the protons and ¹⁹F nuclei on the dumbbell component do not undergo coalescence within the temperature range from 233 to 343 K, an observation which indicates that shuttling does not occur on the NMR time scale (see SI, Section 5). Indeed, the limiting chemical shifts for the slowly exchanging methylene protons a' (6.21 ppm) and a (6.16 ppm) at 343 K allow an estimation²⁵ of the energy barrier which is greater than 17.5 kcal mol⁻¹. This observation is rationalized by the fact that, in addition to the Coulombic repulsion arising from the centrally located BIPY²⁺ unit on the dumbbell component, the introduction of the π -electron-deficient Ar^F units into the dumbbell component presumably further increases the energy barrier, preventing the CBPQT⁴⁺ ring from shuttling.

Radical Cationic States. In order to understand the molecular behavior of the [2]rotaxane in its radical state, cyclic voltammetry (CV) was performed on 1⁶⁺ and 2²⁺. Upon scanning the potential in the negative direction, the dumbbell 2²⁺ undergoes (Figure 2a) a single-electron reduction process at -244 mV, generating the radical state 2^{•+}. This potential, which is significantly higher than that¹⁷ (-460 mV) of the analogous viologen-based compounds having no Ar^F rings, is ascribed to the fact that the BIPY²⁺ unit in 2²⁺ raises its propensity to receive an electron because of the adjacent electron-withdrawing Ar^F rings. In comparison, the highly positively charged [2]rotaxane 1⁶⁺ is more prone to receive electrons: the reduction process occurs in a stepwise manner. In the first instance, it takes up (Figure 2b) two electrons at -143 mV—with one going^{18,24} to the BIPY²⁺ unit in the dumbbell component and the other going to one of the two BIPY²⁺ units in CBPQT⁴⁺—to generate a bis-radical tetracationic species 1^{2+/2(•+)}, an intermediate which is stabilized by the pimerization between the two reduced BIPY^{•+} radical cations. Subsequently, a single electron reduction of the other BIPY²⁺ unit in CBPQT^{2+(•+)} at -217 mV leads to formation of the tris-radical tricationic state 1^{3(•+)}. The anodically shifted reduction potential of this overall three-electron reduction process, in comparison with those of other [2]rotaxanes^{17,24} containing CBPQT⁴⁺ encircling a BIPY²⁺-based dumbbell, can also be ascribed to the electron-withdrawing effect of the Ar^F rings. Following an addition of an excess of Zn dust to the MeCN solution (100 μ M) of 1⁶⁺ and 2²⁺, respectively, the radical cationic states of the [2]rotaxane and the dumbbell were probed by UV/vis/NIR spectroscopy (see SI, Section 6). The spectrum of the dumbbell 2^{•+} displays absorption bands at wavelengths around 400 and 605 nm, both peaks characteristic²⁶ of the BIPY^{•+} radical species. The lack of the NIR absorption indicates that the intermolecular radical-pairing interaction between two dumbbell molecules is very weak at 100 μ M. On the other hand, an absorption band center on 1091 nm—evidence for the formation of the tris-radical tricationic species—is observed in the case of the [2]rotaxane 1^{3(•+)}, which is further confirmed (Figure S9c) as an intramolecular process with the assistance of concentration-dependent UV/vis/NIR experi-

Figure 2. Cyclic voltammograms (CV) of (a) 2²⁺ and (b) 1⁶⁺. A glassy carbon working electrode, a platinum counter electrode, and an Ag/AgCl reference electrode were used in the characterization of 0.5 mM MeCN solutions of these compounds as their PF₆⁻ salts at 298 K with 0.1 M TBAPF₆ serving as the electrolyte. A scan rate of 200 mV·s⁻¹ was used in all the experiments.

ments. Thus, we conclude that, upon the reduction to its tris-radical tricationic state 1^{3(•+)}, the CBPQT^{2(•+)} ring encircles the BIPY^{•+} station on the dumbbell.

Neutral States. The recognition between CBPQT⁽⁰⁾ and the Ar^F rings in the [2]rotaxane in its neutral form was investigated in detail. UV/vis/NIR spectroscopic investigations were performed on the neutral [2]rotaxane and its dumbbell counterpart—namely 1⁽⁰⁾ and 2⁽⁰⁾—which can be generated¹⁶ by titrating the strong chemical reductant cobaltocene (CoCp₂) into both MeCN solutions (50 μ M) of 1⁶⁺ and 2²⁺, respectively, under an Ar atmosphere. Specifically, upon the addition of 1.0 equiv of CoCp₂ to the solution of 2²⁺, the initial colorless solution (Figure 3a, blue trace) turns dark blue, displaying (Figure 3a, purple trace) similar absorption bands to those of the solution of 2²⁺ treated with Zn dust, indicating the rapid formation of the radical state 2^{•+}. After further addition of 5 equiv of CoCp₂ to this solution,²⁷ the reduction from 2^{•+} to 2⁽⁰⁾ was confirmed by the disappearance of the radical absorption band (605 nm) and the concomitant increase of the absorption band at 371 nm, characteristic^{16,28,29} of the neutral BIPY⁽⁰⁾ units (Figure 3a, red trace). A closer examination of the spectra of 2⁽⁰⁾ revealed the presence of a weak absorption

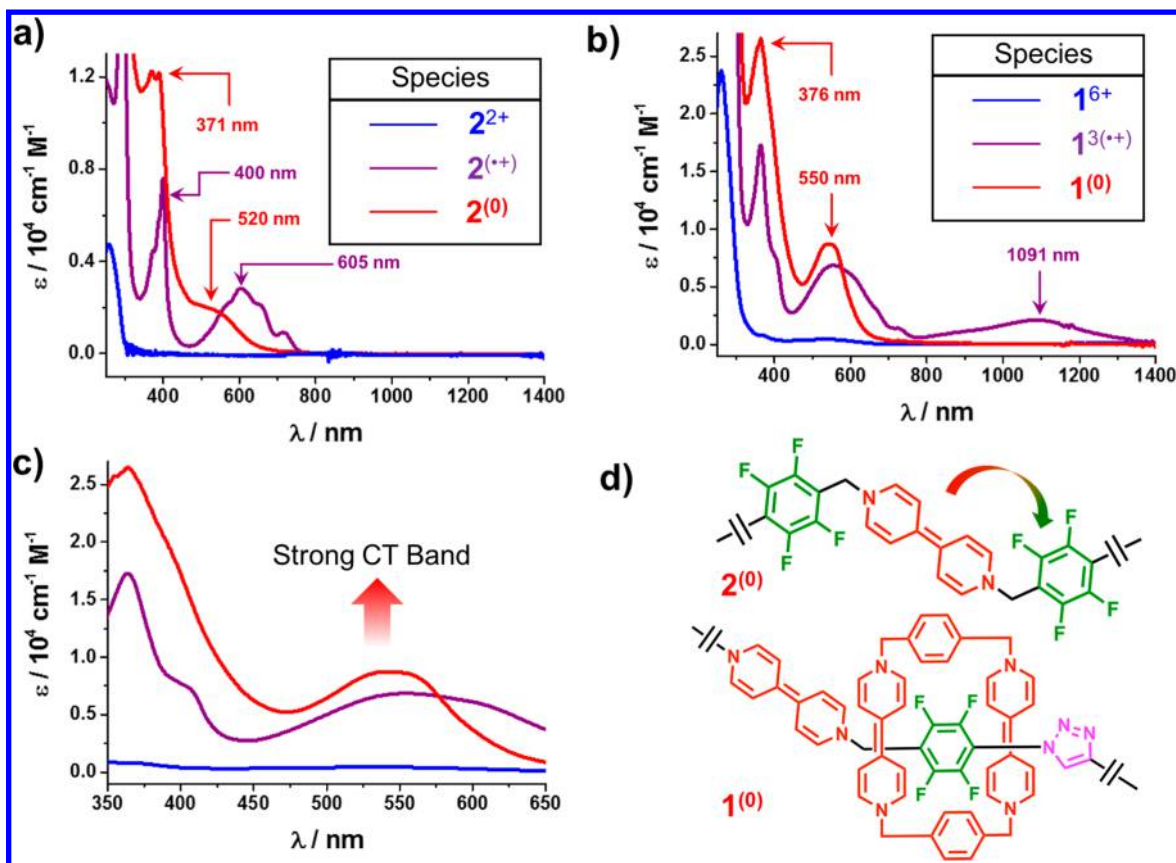

Figure 3. (a) UV/vis/NIR spectra of 2^{2+} and its reduced forms recorded in MeCN solutions ($50 \mu\text{M}$) at room temperature. In order to generate $2^{(\bullet+)}$ and $2^{(0)}$, 1 and 6 equiv of CoCp_2 were added, respectively, to MeCN solutions of 2-2PF $_6$. (b) UV/vis/NIR spectra of 1^{6+} and its reduced forms recorded in MeCN solutions ($50 \mu\text{M}$) at room temperature. In order to generate $1^{3(\bullet+)}$ and $1^{(0)}$, 3 and 11 equiv of CoCp_2 were added, respectively, to MeCN solutions of 1-6PF $_6$. (c) Enlargement of the region between 350 and 650 nm of the spectra in (b), showing the strong charge-transfer band centered on 550 nm. (d) An interpretation of the charge-transfer processes that appear in the spectra of $2^{(0)}$ and $1^{(0)}$.

band at 520 nm—a feature that has not been observed in the previously reported BIPY $^{(0)}$ -containing systems. The reduced forms of the [2]rotaxane were generated by titrating a solution of 1^{6+} with CoCp_2 as well. The conversion of all three BIPY $^{2+}$ units in 1^{6+} to their radical cationic states was achieved (Figure 3b, purple trace) after the addition of 3 equiv of CoCp_2 . The resulting spectrum is characterized by an absorption band at 1091 nm which corresponds to the formation of the tris-radical tricationic species. This absorption band decreased in its intensity upon the further addition of 8 equiv of CoCp_2 , resulting in a new set of peaks at 376 (Figure 3b, red trace) and 550 nm (Figure 3b,c, red trace) which indicate the generation of the neutral species $1^{(0)}$. It should be noted that the absorption band at 550 nm has a much higher extinction coefficient when compared with that of the peak at 520 nm for $2^{(0)}$.

Taking all these observations into account, we have hypothesized that both the absorption bands at 520 nm for $2^{(0)}$ and 550 nm for $1^{(0)}$ result from charge-transfer (CT) interactions. In the case of $2^{(0)}$, the CT process takes place (Figure 3d) intramolecularly between the neutral BIPY $^{(0)}$ and the Ar^{F} units (see SI, Section 9). In contrast, rather than the Ar^{F} units interacting with the BIPY $^{(0)}$ unit on the dumbbell, the mechanically interlocked structure of $1^{(0)}$ allows the Ar^{F} units to interact (Figure 3d) with the neutral CBPQT $^{(0)}$ as a result of its being encircled by the ring. In this manner, CT between the Ar^{F} unit and the two BIPY $^{(0)}$ units in the ring component can take place in a face-to-face manner, while the

shuttling motion of the ring component along the dumbbell makes it possible for the ring to adopt the most optimized conformation so as to maximize these interactions. In other words, CT is facilitated in the case of $1^{(0)}$, giving rise to the significantly higher molar extinction coefficient as well as the 30 nm red-shifted absorption band on going from the neutral dumbbell to the neutral [2]rotaxane. By employing a different reduction protocol (see SI, Section 9), the absorption spectra of these neutral species were also measured in toluene, and shown to be consistent with the observations in MeCN.

The results from CV also help us gain an understanding of the interactions between the Ar^{F} rings and CBPQT $^{(0)}$ in the case of $1^{(0)}$. In analogous viologen-based [2]rotaxanes²⁴ without Ar^{F} rings, the reduction from the tris-radical tricationic state to the neutral state occurs in a stepwise manner, wherein the formation of the bis-radical dicationic intermediate—stabilized by radical-pairing interactions—can be observed. By contrast, the [2]rotaxane $1^{3(\bullet+)}$ undergoes (Figure 2b) a simultaneous three-electron reduction at -686 mV to generate $1^{(0)}$. This observation can be rationalized by the fact that, once one of the BIPY $^{\bullet+}$ units in CBPQT $^{2(\bullet+)}$ is reduced to the neutral state, the ring will move away from the radical recognition site as a result of the interactions between the Ar^{F} rings and the BIPY $^{(0)}$ unit, leading to the collapse of the bis-radical dicationic intermediate so that all the BIPY $^{\bullet+}$ units are reduced simultaneously.

More evidence for the recognition between CBPQT $^{(0)}$ and the π -electron-deficient Ar^{F} rings was obtained from ^1H and

^{19}F NMR spectroscopies. Samples suitable for NMR experiments were prepared¹⁶ (see SI, Section 7) by extracting the neutral species $1^{(0)}$ and $2^{(0)}$ from a biphasic system using $\text{CD}_3\text{C}_6\text{D}_5$ as the organic layer under an Ar atmosphere. By comparing the chemical shifts of the protons and fluorine nuclei in the dumbbell and [2]rotaxane (Figure 4a), we can

Figure 4. (a) Structural formulas of the dumbbell $2^{(0)}$ and the [2]rotaxane $1^{(0)}$, with the protons and fluorine atoms labeled. (b) ^1H NMR (500 MHz, $\text{CD}_3\text{C}_6\text{D}_5$, 298 K) spectra of $1^{(0)}$ and $2^{(0)}$. (c) ^{19}F NMR (470 MHz, $\text{CD}_3\text{C}_6\text{D}_5$, 298 K) spectra of $1^{(0)}$ and $2^{(0)}$. The dashed lines are used to compare the chemical shifts of the signals for the dumbbell $2^{(0)}$ with those of the [2]rotaxane $1^{(0)}$.

characterize the fully reduced [2]rotaxane and identify the recognition sites encircled by the $\text{CBPQT}^{(0)}$ ring in the neutral state. In the case of the dumbbell compound, the reduction from the fully oxidized state 2^{2+} to the neutral state $2^{(0)}$ leads to (Figure 4b) significant upfield chemical shifts of (i) the protons H_α and H_β on the BIPY^{2+} unit, which resonate at 5.47 and 5.60 ppm, respectively, as well as (ii) a signal for the

methylene protons α at around 3.55 ppm, revealing the loss of the aromaticity upon reduction of the BIPY^{2+} unit. In the case of the neutral [2]rotaxane $1^{(0)}$, the presence of a single species was confirmed (Figure S11) by diffusion-ordered ^1H NMR spectroscopy (DOSY), which afforded a diffusion coefficient of $8.2 \times 10^{-10} \text{ m}^2\cdot\text{s}^{-1}$, demonstrating that the mechanically interlocked structure is retained during reduction. All the proton resonances of $1^{(0)}$ can be assigned with the assistance of ^1H – ^1H NOESY spectroscopy. In particular, the peaks for $\text{H}_{\alpha 1}$ and $\text{H}_{\beta 1}$ on the $\text{BIPY}^{(0)}$ units in the $\text{CBPQT}^{(0)}$ ring appear, respectively, at 5.41 and 5.35 ppm (Figure 4c), values which are close to those reported¹⁶ for the free neutral $\text{CBPQT}^{(0)}$. On the other hand, the ^{19}F NMR spectra help us pinpoint the location of the $\text{CBPQT}^{(0)}$ ring component in the neutral state. Notably, the fluorine nuclei resonances for the [2]rotaxane $1^{(0)}$ are shifted (Figure 4c) upfield compared with those for the dumbbell $2^{(0)}$, as a result of shielding by $\text{CBPQT}^{(0)}$ encircling one of the two Ar^{F} rings at any instant in time. In particular, the signal for F_b experiences an upfield shift of 2.34 ppm, which is greater than that (0.46 ppm) of F_a , indicating that F_b resides closer to the center of the cavity of $\text{CBPQT}^{(0)}$ than does F_a . It should also be noted that DNMR shows (see SI, Section 8) only one set of peaks are observed for the protons and fluorine nuclei on the dumbbell component in $1^{(0)}$ over a range of temperatures from 193 to 298 K, demonstrating that $\text{CBPQT}^{(0)}$ undergoes fast shuttling on the NMR time scale along the dumbbell in the neutral state. In the absence of peak separations, a maximal energy barrier of 9.6 kcal mol^{−1} for the shuttling can be estimated.³⁰ Since shuttling of CBPQT^{4+} is slow on the NMR time scale in the fully oxidized form of the [2]rotaxane 1^{6+} , this redox-controllable energy barrier to shuttling paves the way to developing slide-ring-based materials^{31,32} with switchable properties. It should also be noted that the shuttling rate of the ring in its neutral state can be modulated by varying the binding affinity between the recognition sites and the ring; i.e., the higher the binding affinity, the lower the shuttling rate.

COMPUTATIONAL STUDIES

We carried out DFT calculations on the level of M06-2X/6-311G**³³ with zero damping D3 correction³⁴ as implemented in Jaguar 8.2³⁵ (more details can be found in the SI) to characterize the interactions of the CBPQT ring component with the [2]rotaxane in different charge states from its fully oxidized (6+) to the neutral state (0) form. The inclusion of continuum solvent corrections in the DFT is, however, not sufficient to capture the full effect of solvent and cations on the structures and energetics, which become increasingly important in the case of higher charged states, i.e., the radical and the fully oxidized states. As a result, we extracted the charges from the DFT calculations and incorporated them into the UFF universal force field.³⁶ Then we carried out force field based molecular dynamics (MD) simulations including explicit solvent with anions (PF_6^-) for several nanoseconds for each of the charge states and each of the ring positions. These calculations were performed in a box with dimensions of ~ 3.1 , ~ 3.1 , and 4.1 nm in the x , y , and z directions. The final MD relaxed structures are shown in Figure 5.

Next, we used the two-phase thermodynamic (2PT) method³⁷ to calculate the entropy and Gibbs free energy on the basis of the vibrational modes extracted from the Fourier Transform of the velocity autocorrelation function. The final free energies (Figure 5) from these MD simulations reveal that

Redox State	Triazole unit	Ar ^F ring	BIPY ^{•+} unit
6+			
ΔG (kcal mol ⁻¹)	0.00	21.29	19.86
3(•+)			
ΔG (kcal mol ⁻¹)	1.22	10.75	0.00
0			
ΔG (kcal mol ⁻¹)	12.21	0.00	7.46

Figure 5. Simulated co-conformations of the [2]rotaxane at different oxidation states and their relative energy levels. In each oxidation state, the energy of the most stable co-conformation is assigned to be 0 kcal mol⁻¹.

the most stable sites are triazole units, BIPY^{•+} unit, and Ar^F rings in the case of the fully oxidized, the radical, and the neutral states, respectively. The results are consistent with the experimental observations. In addition, the energy barrier for the CBPQT ring to shuttle along the dumbbell component can be estimated by comparing the differences in free energies for various binding sites: the energy barriers are 21.29 and 7.46 kcal mol⁻¹ in the case of the fully oxidized and the neutral states, respectively. These barriers are in line with the values obtained from dynamic NMR spectroscopy.

CONCLUSIONS

We have investigated the shuttling of the CBPQT ring component in a tri-stable [2]rotaxane in different oxidation states and demonstrated (Table 1) how this mechanically

interlocked molecule experiences three different kinds of molecular recognition. The reduction of the ring component from CBPQT⁴⁺ to CBPQT^{2(•+)} to CBPQT⁽⁰⁾ alters its affinity toward the five recognition sites on the dumbbell components, leading to the ring component preferentially encircling (Figure 6) the triazole, BIPY^{•+}, and Ar^F units, respectively.

Figure 6. Graphical summary of the actuating processes with the energy levels involved in the [2]rotaxane as a result of changes in its redox state. (a) In the fully oxidized state, the CBPQT⁴⁺ ring encircles the triazole unit and does not shuttle along the dumbbell component on either the ¹H or the ¹⁹F NMR time scales. In the radical state, the CBPQT^{2(•+)} ring interacts with the BIPY^{•+} unit and gives rise to the formation of a tris-radical tricationic species. In the neutral state, the CBPQT⁽⁰⁾ ring recognizes the electron-deficient Ar^F recognition sites, forming a charge-transfer complex. The ring shuttles quickly along the dumbbell component because of the removal of the Coulombic repulsion present in the fully oxidized state. (b) The energy profiles for the [2]rotaxane in different redox states when the ring shuttles along the dumbbell component. The lines in pink, blue, purple, red, and green correspond to the recognition units shown in (a).

Significantly, the discovery of stabilizing interactions between the CBPQT⁽⁰⁾ ring and the π -electron-deficient Ar^F units—as experimentally confirmed by ¹H, ¹⁹F NMR, and UV/vis/NIR spectroscopies and electrochemical studies, and computationally proved by DFT-based MD calculations—introduces an additional recognition site into CBPQT-containing rotaxanes. The design of this rotaxane, which demonstrates that an otherwise very weak interaction between the recognition unit and the ring upon reduction to the fully reduced state can be enhanced, supports the notion of neighboring component effect, and it is more than likely that this ubiquitous tenet of conformational analysis in the more traditional areas of

stereochemistry and physical organic chemistry should surface within the context of presumably other mechanically interlocked molecules.

- (25) The minimal energy barrier for the ring component to come across at temperature T is estimated by using the equation $\Delta G_c^\ddagger = aT[9.972 + \log(T_c/\Delta\nu)]$, where T_c is the coalescence temperature, $\Delta\nu = 25$ is the peak separation of proton a and a' in MHz, constant $a = 4.575 \times 10^{-3}$ for units of kcal mol⁻¹. By applying $T = T_c = 343$ K, the minimal energy barrier is calculated as 17.5 kcal mol⁻¹.

- (29) Fernando, I. R.; Frasconi, M.; Wu, Y.; Liu, W.-G.; Wasielewski, M. R.; Goddard, W. A., III; Stoddart, J. F. *J. Am. Chem. Soc.* **2016**, 138, 10214–10225.
- (30) From the equation $\Delta G_c^\ddagger = aT[9.972 + \log(T_c/\Delta\nu)]$, one can see that $\log(T_c/\Delta\nu)$ is considerable compared with 9.972 only when $\Delta\nu$ is small enough. As a result, we take $\Delta\nu = 25$ MHz, i.e., $\Delta\delta = 0.05$ ppm and $T = T_c = 193$ K to calculate the energy barrier, which is 9.6 kcal mol⁻¹.
