Just Accepted

"Just Accepted" manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides "Just Accepted" as a service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. "Just Accepted" manuscripts appear in full in PDF format accompanied by an HTML abstract. "Just Accepted" manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are citable by the Digital Object Identifier (DOI®). "Just Accepted" is an optional service offered to authors. Therefore, the "Just Accepted" Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the "Just Accepted" Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these "Just Accepted" manuscripts.

Abstract

Bimetallic electrocatalysts provide a promising strategy for improving performance, especially in the enhancement of selectivity of CO₂ reduction reactions. However, the first step of CO₂ activation on bimetallic materials remains obscure. Considering bimetallic silver-copper (AgCu) as an example, we coupled ambient pressure X-ray photoelectron spectroscopy (APXPS) and quantum mechanics (QMs) to examine CO₂ adsorption and activation on AgCu exposed to CO₂ with and without H₂O at 298 K. The interplay between adsorbed species and the surface alloy composition of Cu and Ag is studied in atomic details. The APXPS experiment as well as DFT calculations indicate that the clean sample has an Ag rich surface layer. Upon adsorption of CO₂ and surface O, we found that it is thermodynamically more favorable to induce subsurface Cu to substitute for some surface Ag atoms, modifying the stability and activation of CO₂ related chemisorbed species. We further characterized this substitution effect by correlating the new adsorption species with the observed binding energy shift and intensity change in APXPS.

Converting carbon dioxide (CO_2) into liquid fuels and feedstock chemicals is an attractive approach to close the anthropogenic carbon cycle while creating new energy cycles for storing renewable energy in the form of hydrocarbon-based energy-dense fuels.¹⁻⁵ Advanced electrocatalysts are required to convert inert CO_2 to various hydrocarbon-based chemicals.⁶⁻⁷ An emerging design principle is to utilize multicomponent materials to promote the CO_2 reduction reaction (CO₂RR). Typically in a bimetal system, one metal has high selectivity for producing CO (such as Ag and Au)⁸⁻¹³, while the other metal is Cu,¹³⁻¹⁶ the only metal that has been shown to reduce CO to multi-carbon products.¹⁷ Recently, the silver-copper (AgCu) catalyst has demonstrated a dramatic improvement in product selectivity and activity compared to pure Cu catalyst.¹⁸⁻²¹ However, the bimetal systems underlying CO₂RR activation mechanism responsible for the enhanced catalytic performance remains unclear. Various reaction mechanisms have been suggested based on preconceived notions of the material properties and reaction mechanisms. To optimize such alloy systems, it is essential to develop a comprehensive atomistic level understanding of how CO_2 is activated by alloy catalyst surfaces.

CO₂RR is complex, involving applied potential, ions in the electrolyte, pH value of the electrolyte and many other factors. Given this complexity, we wanted to decouple this catalytic process into CO_2 adsorption/activation (presumably gas-phase dominated), and sequential reaction steps (presumably dominated by electrochemical conditions). In this work, we aim to understand the first steps of CO_2 adsorption/activation on AgCu bimetallic surface, focusing on fundamental questions regarding identification of the active species/sites, the functionality of each metal sites, and the catalyst structural evolution that remain unexamined.

We previously explored the dramatically different CO_2 adsorption and activation behaviors observed on pure Cu and Ag surfaces at 298 K.²²⁻²⁴ On a Cu surface, gaseous CO_2 ($g\text{-CO}_2$) is stabilized on the surface as physisorbed linear CO_2 ($l\text{-CO}_2$), and then converted to chemisorbed bent CO_2 ($b\text{-CO}_2$) by forming hydrogen bonds (HBs) with surface adsorbed H_2O .²²⁻²³ In contrast, on an Ag surface, $g\text{-CO}_2$ reacts with surface O to form a chemisorbed surface species ($\text{O}=\text{CO}_2^{\delta-}$), which stabilizes up to four water molecules through HBs with $\text{O}=\text{CO}_2^{\delta-}$. In addition, chemisorbed $b\text{-CO}_2$ is also stabilized on the Ag by HBs from two waters.²⁴ These dramatic differences of CO_2 interacting with Ag or Cu surfaces motivates this study, to understand how CO_2 interacts with the AgCu surface alloy.

In this work, we combined *in-situ* ambient pressure X-ray photoelectron spectroscopy (APXPS) with quantum mechanics (QM) to obtain a comprehensive understanding of how CO_2 and H_2O interact with the

1
2
3 AgCu surface to initiate CO₂ adsorption and activation. Our findings are summarized in **Figure 1**. We found
4 both O=CO₂^{δ-} and *l*-CO₂ are stable on the AgCu surface exposed solely to 0.3 Torr CO₂. On the other hand,
5 (O=CO₂^{δ-})-(H₂O)₁₋₄ and (*b*-CO₂)-(H₂O)₂ form on AgCu when 0.15 Torr H₂O is combined with 0.3 Torr
6 CO₂. Due to the interplay between Ag and Cu at the surface, adsorbates on AgCu have different geometrical
7 and electronic structures as exhibited in the C 1s binding energy (BE) shifts compared to those on pure Ag
8 and Cu. We also observed that chemistry driven surface reconstruction for the AgCu bimetallic system,
9 induced by surface adsorption, changes the Ag and Cu distribution on the surface as well as the CO₂ surface
10 adsorption configuration. We observed the formation of surface O when these systems are exposed to CO₂
11 or H₂O, which may arise from dissociative reactions on the Ag sites. We observed that this surface O then
12 attracts subsurface Cu to the surface, promoting Cu substitution of Ag in the surface layer. This chemistry
13 driven surface reconstruction process is shown in **Figure 2** and **3**. A small amount of surface O is involved
14 in the surface reconstruction. However, the current AgCu system differs from the extensively reported
15 metal-metal oxide systems.²⁵⁻³¹ The bimetallic surface exhibits a synergetic effect between the Ag and Cu
16 surface composition that tunes the CO₂ (H₂O)-AgCu interactions, initiating surface reconstruction, and
17 altering the CO₂ activation process. Thus, CO₂ adsorption and activation on AgCu surfaces operates entirely
18 differently compared to pure Ag or Cu surface, providing possibilities for further tuning CO₂ adsorption
19 behavior to facilitate selective product formation.

30 2. Methods:

31 32 33 34 2.1 Sample preparation:

35 The AgCu bimetal samples were made by a physical melting method. First, Ag (99.999%) and Cu (99.999%)
36 were melted in the atomic ratio of 1:4 under argon (Ar) in a vacuum arc furnace; following, the molten
37 mixtures were quenching in the deionized (DI) water and cold-rolled into foils; lastly, the foils were
38 polished with sandpapers (600, 1200, and 2500 grit 3M) and cleaned with DI water and Ethanol. The
39 samples showed (111) surface orientation after treatment.²¹ The samples were cut to size of 8 × 8 mm² to
40 fit the sample holder and transferred to a vacuum chamber with base pressure of 8×10⁻¹⁰ Torr at beamline
41 9.3.2 at Advanced Light Source (ALS), Lawrence Berkeley National Laboratory (LBNL). The sample
42 surface was cleaned by repeated Ar sputtering and rapid low temperature thermal annealing. Ar sputtering
43 was performed using 8×10⁻⁶ Torr Ar gas (2 kV, 20 mA) for 1 hour in the first 2 cycles. The thermal treatment
44 was performed by increasing the temperature rapid to ~400 K, holding the temperature for 5 mins, and then
45 cooling down the sample to room temperature in the first 2 cycles. For the last treatment cycle, a mild Ar
46 sputtering was performed (1.5 kV, 10 mA) for 30 mins, while a rapid thermal treatment was done by
47 increasing the temperature to ~350 K, holding the temperature for 1 min, and then cooling down the sample
48

to room temperature. With these surface treatments, the surface condition can be restored regardless of the initial surface conditions. Starting from this initial surface, the AgCu sample was heated at 450 K for 5 mins to get an Ag-rich surface. We denoted the initial- and heat-treated sample as Ag-lean and Ag-rich AgCu samples, respectively.

2.2 APXPS measurements:

Ambient pressure XPS measurements were performed at beamline 9.3.2 of the ALS, LBNL.³² The samples were cleaned in the preparation chamber of the beamline and transferred to the main chamber for further characterization and *in-situ* gas adsorption experiments. The APXPS spectra were collected in the following order: a low-resolution survey scan with a binding energy of 600 eV to -5 eV at photon energy of 670 eV, then high-resolution scans of O 1s, C 1s, Ag 3d and Cu 3p at different photon energies. For each condition, samples were equilibrated for at least 30 mins before the measurement. The C 1s and O 1s signals representing the surface adsorbates properties were taken with photon energies of 415 eV and 670 eV, respectively, to get a surface sensitive probe with the photoelectron kinetic energy of ~130 eV. Due to the beamline limitation, we cannot take Cu 3p (and/or Cu 2p) spectra with 130 eV photoelectron kinetic energy. Thus, we used 670 eV and 800 eV, and 380 eV and 510 eV photon energies to monitor the Ag 3d and Cu 3p signals at surface and bulk, respectively. The catalyst components distribution at the surface was quantified using the same kinetic energies probe by first normalizing the raw signals to the beam flux and then applying the cross-section factors. By taking spectra at different sample spots and comparing spectra before and after beam illumination for 2 hours, we found beam damage on the sample is negligible during the measurements.

The gas adsorption experiments were performed at 298 K with APXPS recorded. The CO₂ partial pressure was kept at 0.3 Torr for CO₂ adsorption, whereas the total pressure was kept at 0.45 Torr with 0.3 Torr CO₂ and 0.15 Torr H₂O. The H₂O was degassed using the freeze-pump-thaw method for three cycles to ensure no dissolved gases. All the gas-lines were well cleaned and baked before dosing gases. The dosing gas (CO₂, H₂O) purities were *in-situ* monitored by a conventional quadrupole mass spectrometer to ensure no additional gas cross-contamination (especially, the CO and H₂ gases).

2.3 QM predictions:

Since the AgCu samples were made through high temperature treatments, we expect that the surface prefers the (111) surface for both fcc metals, as established experimentally.²¹ Thus, the QM studies assume the (111) surface, which we describe using a 4 × 4 supercell. We include 4 (111) layers in which the bottom 2 are fixed. We left 15 Å in the z direction to avoid interaction between periodic cells. The convergence test

1
2
3 with 4–7 layers and vacuum region of 10 Å were conducted and the results are shown in **Table S1**. The top
4 two layers were relaxed, and the bottom layers were fixed during the optimization. We found that all
5 structures of adsorbed O=CO₂^{δ-} species are maintained, and the adsorption energy is on average -0.74 eV
6 (*E*) and -0.27 eV (*G*), which is very close to the values that we obtained assuming the 4-layer structures.
7 The 4-layer model is sufficiently reliable to represent the properties of these periodic systems.
8
9

10
11 All calculations were carried out with the Vienna *Ab-initio* Simulation Package (VASP).³³ We used the
12 Perdew–Burke–Ernzerhof (PBE) formulation of the generalized gradient approximation (GGA) exchange-
13 correlation functional using the projector-augmented (PAW) method and including the D3 (Grimme, Becke,
14 and Johnson) empirical corrections for long-range London dispersion.^{34–36} A plane-wave basis set cutoff of
15 600 eV and an energy smearing of 0.2 eV using the first order Methfessel–Paxton scheme were employed.³⁷
16 The electron self-consistent calculations are considered to be converged when the energy differences are
17 less than 10⁻⁶ eV. The structure optimizations are considered converged when force differences are less
18 than 10⁻⁴ eV Å⁻¹. Reciprocal space was sampled by a Γ-centered Monkhorst-Pack 3 × 3 × 1 scheme for all
19 calculations. More details can be found in the previous study²⁴ and in the supporting information.
20
21

22 3. Results

23 3.1 Clean AgCu surface with no adsorbates

24 Using APXPS we examined two different AgCu surface ratios under vacuum at 298 K prior to CO₂
25 adsorption. From the spectra we know that there is no inner charge transfer between Ag and Cu in AgCu
26 (**Figure S1**).^{21,38} Quantified by APXPS under vacuum at 298 K, the Ag-lean samples have Ag:Cu ratio of
27 0.2:1 while the Ag-rich samples have 0.7:1, over the top ~2.4 nm layer, becoming 0.1:1 and 0.3:1,
28 respectively, over the top ~3.6 nm layer (**Figure S1**). This enrichment of Ag at the surface indicates that
29 Ag atoms prefer the surface compared to bulk in the AgCu matrix under vacuum, which is expected from
30 the low surface energy of Ag (1250 mJ/m²) compared to Cu (1830 mJ/m²).³⁹ Our QM predictions also found
31 it 0.18 eV more favorable for Cu to be doped in the bulk compared to the surface (**Figure S2**) under vacuum
32 at 298 K, justifying our simulation model which started with pure Ag in the outer most surface layer. This
33 is further verified by heating the AgCu sample, which results in Ag migration to the surface (**Figure S1** and
34 **Figure S3**).
35
36

37 3.2 CO₂ adsorption on AgCu surfaces

38 We first determined which species are stable on Ag and Cu exposed to CO₂, namely O=CO₂^{δ-} on Ag and
39 *l*-CO₂ on Cu,^{22,24} and we evaluated their stabilities on the new bimetallic AgCu surface, while gradually
40
41

doping more and more surface Cu atoms into the Ag surface. We reported earlier that CO₂ adsorbs on Ag surface to form O=CO₂^{δ-} with two O atoms on the surface interacting with five Ag atoms and the C=O double bond pointing away from the surface. Our QM predictions found that replacing Ag atoms with Cu atoms modifies the surface O=CO₂^{δ-} properties. Since one surface O can attract up to three Cu atoms to the surface (**Figure S4**), we considered the systematic substitution of three Ag atoms with Cu underneath a surface O. The only stable O=CO₂^{δ-} configuration on the AgCu matrix has one Cu replacing the Ag atom under the C atom, leading to E_{ads} = -0.55 eV and ΔG = -0.08 eV (**Figure 1a**), while having one Cu under the O atom or having two or three Cu atoms substituted for Ag in the surface destabilize O=CO₂^{δ-}. With O=CO₂^{δ-} on the AgCu surface, it interacts closely with five catalyst atoms (**Figure S5**). Thus, we denote this stable configuration as (O=CO₂^{δ-})-(4Ag1Cu).

We found that (O=CO₂^{δ-})-(4Ag1Cu) has a C=O_{up} double bond (with a length of 1.22 Å) pointing up normal to the surface while the other two O bind to two-Ag and one-Cu with C-O lengths of 1.36 Å, similar to that on Ag. We observed that (O=CO₂^{δ-})-(4Ag1Cu) has two O-Ag distances of 2.43 Å and 2.39 Å while the O-Cu distance is 2.12 Å. Those distances are smaller than on pure Ag which exhibited three O-Ag distances of 2.65 Å, 2.38 Å, and 2.28 Å. The slightly modified geometry leads to a change in the charge distribution on the O=CO₂^{δ-} compared to that on Ag. Bader charge analyses⁴⁰⁻⁴¹ showed that the total charge of O=CO₂^{δ-} on AgCu is -1.16e with a C charge of +1.53e, compared to a total charge of -1.26e and carbon charge of +1.47e on the pure Ag(111) surface. The increased positive charge on the C atom leads to a predicted C 1s binding energy (BE) +0.34 eV higher than that for the Ag surface, leading to a predicted experimental C 1s BE of 288.2 eV compared to 287.9 eV on pure Ag surface (**Figure 1b,c**). We also tested the stability of O=CO₂^{δ-} on AgCu with Cu at the 2nd and 3rd layer (**Table S2**). We found that Cu atoms prefer to stay on the surface when adsorbents such as O and O=CO₂^{δ-} are present. Having Cu atoms buried inside the Ag matrix does not affect the adsorption geometry nor XPS binding energy.

For *l*-CO₂, our QM predictions found that at least two surface Cu atoms combined with a subsurface O is required to stabilize *l*-CO₂ on the AgCu surface. Since the surface prefers to have Ag, a surface O is required to bring these two Cu atoms to the surface (**Figure S2**). Thus, we denoted this stable configuration as (*l*-CO₂)-(2Ag2Cu1O_{surf}1O_{sub}) (**Figure S5**). With surface O and two adjacent Cu atoms in the Ag matrix, we found that *l*-CO₂ prefers to be perpendicular to the Cu pair (**Figure 1a**), rather than parallel (**Figure S6**). This stable configuration is 3.32 Å above the surface with E_{ads} = -0.54 eV, ΔG = -0.06 eV. The predicted C 1s BE is +0.2 eV higher than *l*-CO₂ on Cu, which is found experimentally to be at 288.6 eV (**Figure 1b,c**).

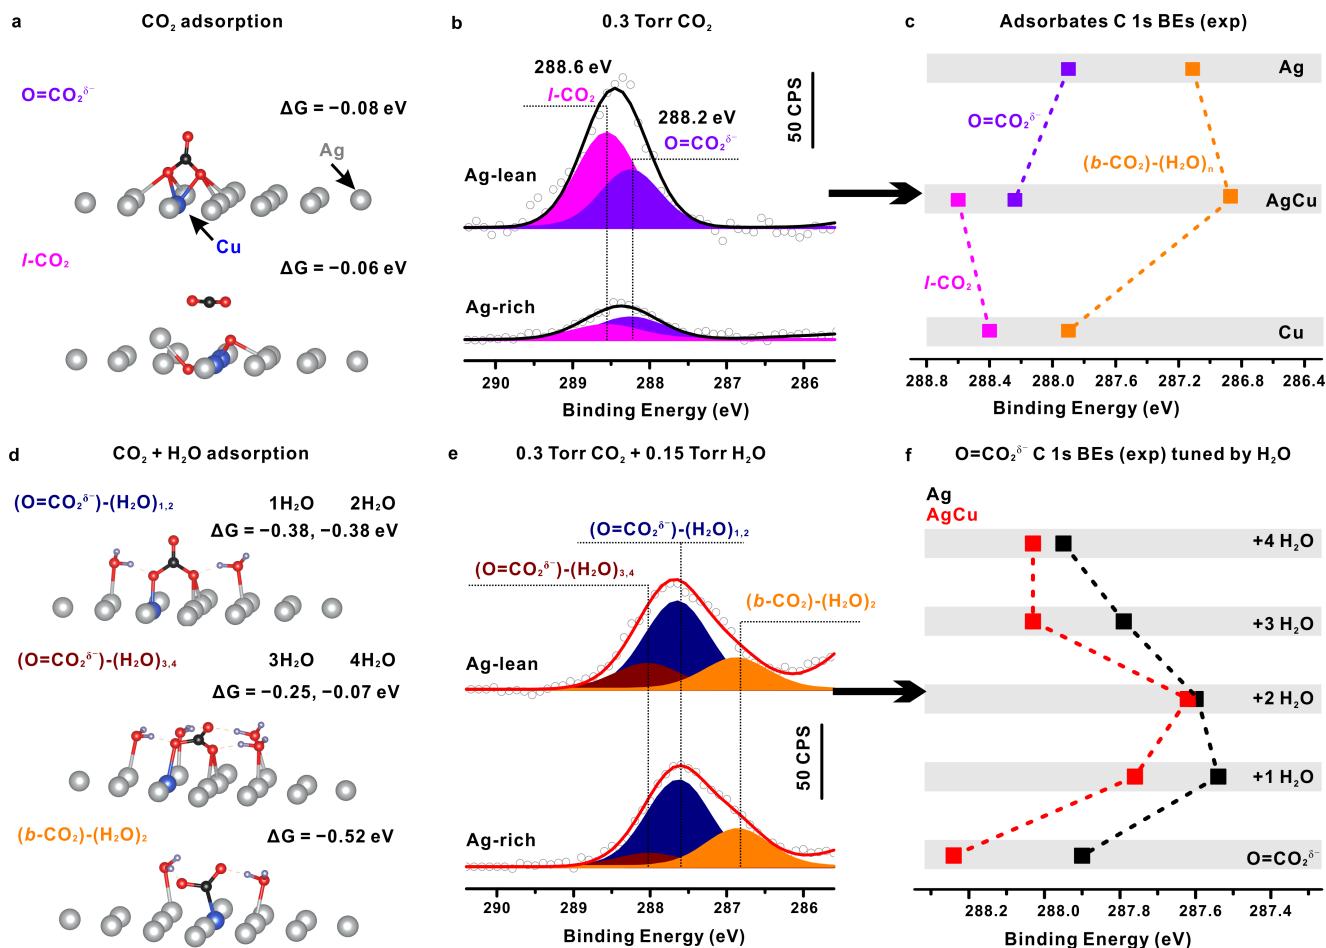

Figure 1. The QM predictions and experimental observations of AgCu surface with CO₂ adsorption alone and in the presence of H₂O at 298 K. **(a)** Predicted structures for adsorbates, O=CO₂^{δ-} and l-CO₂, on AgCu surface exposed to 0.3 Torr CO₂. **(b)** The C 1s APXPS spectra for adsorbates on AgCu surfaces in the presence of 0.3 Torr CO₂ at 298 K. To deconvolute the experimental peak we assume that the two C 1s peaks arising from O=CO₂^{δ-} and l-CO₂ are separated by 0.4 eV as found with QM predictions. **(c)** The experimental C 1s BEs of various adsorbates on Ag, Cu, and AgCu surfaces. The adsorbate BEs change for different surfaces shows the tunability of adsorbates properties from altered gas-catalyst interaction. **(d)** Predicted structures for adsorbates, (O=CO₂^{δ-})-(H₂O)_{1,2} and (b-CO₂)-(H₂O)₂, on AgCu surface exposed to 0.3 Torr CO₂ and 0.15 Torr H₂O. The adsorbed O=CO₂^{δ-} species stabilizes one or two H₂O_{ad} via HBs to the O on surface and two more water with HBs to the C=O. The b-CO₂ becomes stabilized by a pair of H₂O_{ad} each forming a HB with an O of b-CO₂. **(e)** The C 1s APXPS spectra for adsorbates on AgCu surfaces in the presence of 0.3 Torr CO₂ and 0.15 Torr H₂O at 298 K. The peak separations used for this deconvolution were determined from the theory. **(f)** The experimental C 1s BE changes for O=CO₂^{δ-} without and with 1 to 4 H₂O on Ag and AgCu surfaces.

The C 1s spectra of AgCu surfaces exposed to CO₂ showed a spectral shape similar to those on Ag but not on Cu (**Figure 1b**, and **Figure S7**).^{22, 24} The adsorbate peak in the region from 286 eV to 290 eV shifted

and broadened significantly compared to pure Cu or Ag.^{24,27} The full width at half maximum (FWHM) on AgCu is ~1.2 eV, significantly larger than ~0.8 eV obtained on Ag surfaces, indicating more than one adsorbate resides on the AgCu surface after exposure to CO₂.

Using the ΔBE predicted from the QM, we de-convoluted the C 1s spectra of the AgCu surface into two peaks: O=CO₂^{δ-} at 288.2 eV and *l*-CO₂ at 288.6 eV (**Figure 1b**). We calculated the ratio of (O=CO₂^{δ-})-(4Ag1Cu) to (*l*-CO₂)-(2Ag2Cu1O_{surf}) to be ~1.5:1 on Ag-rich and ~0.6:1 on Ag-lean surfaces. The larger population of (O=CO₂^{δ-})-(4Ag1Cu) than (*l*-CO₂)-(2Ag2Cu1O_{surf}) on Ag-rich surfaces is consistent with that O=CO₂^{δ-} and *l*-CO₂ dominating the adsorption of CO₂ on Ag and Cu, respectively. The change of O=CO₂^{δ-} and *l*-CO₂ populations on surfaces with different AgCu compositions (**Figure 1b**) and the shifts in C 1s BEs with respect to pure Ag and Cu (**Figure 1c**) demonstrate the tunability of the surface alloy composition to the surface adsorbates.

3.3 CO₂ adsorption on AgCu surfaces modified by surface H₂O

We next evaluated the CO₂ adsorption in the presence of H₂O on AgCu surfaces. QM found that surface H₂O makes HBs both to chemisorbed O=CO₂^{δ-} and to physisorbed *l*-CO₂ on AgCu. On AgCu, O=CO₂^{δ-} stabilizes up to four H₂O, with the first two H₂O forming HBs to each O bonded to the surface, and the 3rd and 4th H₂O making HBs to the two sp² lone pairs on the C=O unit (**Figure 1d**). On AgCu, the attachment of successive *n*H₂O (*n* = 1 – 4) to O=CO₂^{δ-} leads to ΔG = -0.38 eV, -0.38 eV, -0.25 eV, and -0.07 eV, respectively. The first two H₂O bonding to the O linkage to Ag lead to little change in the geometry, while the 3rd and 4th H₂O force the C=O bond to rotate from being perpendicular to the surface to tilting nearly parallel to the surface. The QM predicted C 1s BEs are 269.31 eV, 269.17 eV, 269.58 eV, and 269.56 eV, respectively. It is worth noting that QM predicts the ΔBE rather than the absolute BE, therefore to convert QM predicted BE to values that are experimentally observed (**Figure 1f**), a rigid shift of ~18.5 eV should be added. Moreover, starting with the different C 1s BEs of O=CO₂^{δ-} on Ag and AgCu, we found that attaching two H₂O or four H₂O onto the O=CO₂^{δ-} lead to almost the same BEs on both surfaces (**Figure 1f**), indicating that surface H₂O may help balance and redistribute the surface adsorbate charge to reach a stable state. The energetics clearly show the tunability of the surface adsorbate properties, and how they can be easily modified by surface H₂O.

On both pure Ag and Cu surfaces, we observed that surface water stabilizes the *b*-CO₂. The same behavior occurred on the AgCu surface, with *b*-CO₂ stabilized by forming HBs with two waters, where two H₂O are on Ag sites and the carbon of *b*-CO₂ is on the Cu site. The (*b*-CO₂)-(H₂O)₂ on the Ag matrix with 1Cu substituted has ΔG = -0.52 eV (**Figure 1d**) and a QM C 1s BE = -268.42 eV.

Using the QM predicted ΔBE , we were able to resolve the experimental peaks for the $(O=CO_2^{\delta-})-(H_2O)_{1-4}$ and $(b-CO_2)-(H_2O)_2$ on AgCu, leading to 287.76 eV, 287.62 eV, 288.03 eV and 288.03 eV, and 286.87 eV, respectively. Accordingly, we used three components, $(O=CO_2^{\delta-})-(H_2O)_{1,2}$ (with an indistinguishable BE difference of 0.1 eV), $(O=CO_2^{\delta-})-(H_2O)_{3,4}$, and $(b-CO_2)-(H_2O)_2$, to de-conolute the adsorbate peak. The spectral fitting results show that the surface is dominated by $(O=CO_2^{\delta-})-(H_2O)_{1,2}$ and $(b-CO_2)-(H_2O)_2$. We obtained a higher population of $(b-CO_2)-(H_2O)_2$ on AgCu surface compared to that on Ag surface, indicating the change of the surface chemistry, which is consistent with Cu promoting the formation of $b-CO_2$.^{22-23, 42} This strong agreement between the QM predictions and experimental observations validates the accuracy of the surface adsorbate assignments.

3.4 Surface reconstruction induced by CO₂ adsorption and further altered gas adsorption

Experimentally, we have observed $(O=CO_2^{\delta-})-(5Ag)$ at 287.9 eV on pure Ag, but we do not find such a peak on the AgCu alloy surface (**Figure 1b**). This discrepancy is explained by the surface substitution of subsurface Cu to surface Ag upon the adsorption of gases species. We find that CO₂ adsorption induces a transformation of the AgCu surface configuration (**Figure 2**). For pristine AgCu samples with no gas adsorption (essentially under ultra-high vacuum), Ag is 0.18 eV more favorable to stay at the outermost surface layer than Cu (**Figure S2**). Since surface O is required to form $O=CO_2^{\delta-}$ on the surface, we calculated the thermodynamics driving forces controlling how a surface O forms on the outmost Ag layer and how the AgCu surface reconstruction is initiated. For the AgCu surface with adsorbed $O=CO_2^{\delta-}$, we consider the changes of the top two layers and the 5 atoms that interact closely with $O=CO_2^{\delta-}$ (**Figure 2a**). With O and CO₂ on the surface, the initial surface configuration is $(CO_2-O_{surf})-(5Ag)_{surf}(1Cu4Ag)_{sub}$, which then evolves along two reaction pathways:

- (1) $O=CO_2^{\delta-}$ forms directly on $(5Ag)_{surf}(1Cu4Ag)_{sub}$ with $\Delta G = -0.28$ eV; and
- (2) Surface O attracts one Cu atom from the subsurface to substitute for one surface Ag atom with $\Delta G = -0.45$ eV, and then the surface O reacts with CO₂ to form $O=CO_2^{\delta-}$ on $(4Ag1Cu)_{surf}(5Ag)_{sub}$ with $\Delta G = -0.08$ eV.

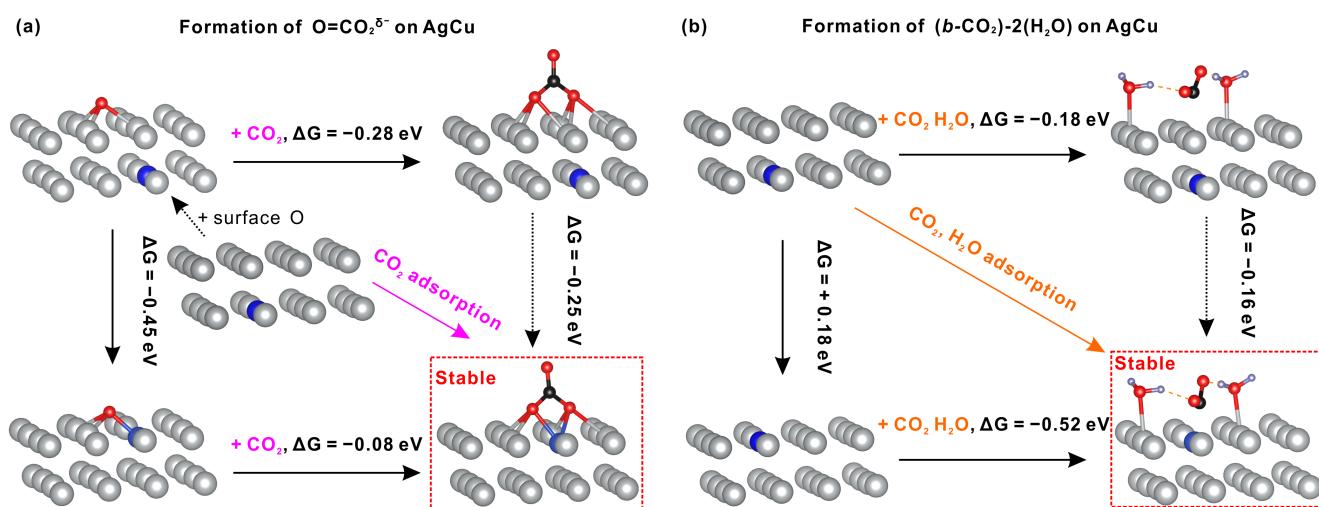

Figure 2. The overall energy landscape of adsorbate formation on the AgCu surface with CO_2 adsorption alone and in the presence of H_2O at 298 K. (a) The formation of $\text{O}=\text{CO}_2^{\delta-}$ on AgCu surface. Starting with only Ag atoms as the first layer, surface O brings Cu to the surface to form the AgCu matrix, $\Delta G = -0.45 \text{ eV}$. Considering both chemistry driven surface reconstruction and adsorbate stability, we find that $\text{O}=\text{CO}_2^{\delta-}$ on 4Ag1Cu matrix is 0.25 eV more stable than on 5Ag. **(b)** The formation of $(b\text{-CO}_2)\text{-}(\text{H}_2\text{O})_2$ on the AgCu surface. When co-dosing H_2O and CO_2 , the most stable end result would be $(b\text{-CO}_2)\text{-}(\text{H}_2\text{O})_2$ on $(7\text{Ag1Cu})_{\text{surf}}(8\text{Ag})_{\text{sub}}$. We found that adsorption of $b\text{-CO}_2$ with H_2O under experimental condition has a $\Delta G = -0.52 \text{ eV}$. Considering both chemistry driven surface reconstruction and adsorbate stability, we found that $(b\text{-CO}_2)\text{-}(\text{H}_2\text{O})_2$ on $(7\text{Ag1Cu})_{\text{surf}}(8\text{Ag})_{\text{sub}}$ is 0.16 eV more stable than on $8(\text{Ag})_{\text{surf}}(7\text{Ag1Cu})_{\text{sub}}$.

Considering that surface O prefers by 0.45 eV to adsorb on a Cu site rather than an Ag site (**Figure S2**), reaction pathway (2) has a relative free energy of $(-0.45) + (-0.08) - (-0.28) = -0.25 \text{ eV}$ compared to reaction pathway (1) (**Figure 2a**). Thus, case (2) with formation of $\text{O}=\text{CO}_2^{\delta-}$ on the AgCu surface having 4Ag and 1Cu is energetically more favorable by 0.25 eV than case (1) with formation of $\text{O}=\text{CO}_2^{\delta-}$ on AgCu surface having 5Ag sites.

Similarly, $(b\text{-CO}_2)\text{-}(\text{H}_2\text{O})_2$ on AgCu is only stable when one subsurface Cu atom substitutes for one surface Ag atom (**Figure 2b**). We considered the changes of the top two layers and the eight atoms that interact closely with $(b\text{-CO}_2)\text{-}(\text{H}_2\text{O})_2$ (**Figure 1d**, and **Figure S5**). We find that $(b\text{-CO}_2)\text{-}(\text{H}_2\text{O})_2$ lands on $(8\text{Ag})_{\text{surf}}(1\text{Cu7Ag})_{\text{sub}}$ with a $\Delta G = -0.18 \text{ eV}$, however, this also draws one subsurface Cu to the surface, with $\Delta G = -0.18 \text{ eV}$ to form a more stable configuration: $(b\text{-CO}_2)\text{-}(\text{H}_2\text{O})_2$ on $(7\text{Ag1Cu})_{\text{surf}}(8\text{Ag})_{\text{sub}}$ with $\Delta G = -0.52 \text{ eV}$. This process has a total free energy of $(-0.52) - (-0.18) - (-0.18) = -0.16 \text{ eV}$ (**Figure 2b**), leading to the $(b\text{-CO}_2)\text{-}(\text{H}_2\text{O})_2$ on $(7\text{Ag1Cu})_{\text{surf}}(8\text{Ag})_{\text{sub}}$ the stable configuration.

The chemistry driven surface reconstruction is validated experimentally by the Ag 3d and Cu 3p spectroscopic intensity changes (**Figure 3**, **Figure S8**). The Ag 3d and Cu 3p signals were collected under photon energies of 670 eV and 380 eV to have the same depth profile. We find that after CO₂ adsorption on Ag-rich AgCu surface, the Cu 3p signal increased, while the Ag 3d signal decreased. This is due the migration of Cu to the surface and the signal attenuation from the adsorbate layer (**Figure 3a**). The increase of Cu 3p by 135.1% after CO₂ adsorption for the Ag-rich AgCu surface is a strong indicator of the surface reconstruction. On the contrary, the Cu signal decreases on the Ag-lean surface (**Figure S8**), mainly because of signal attenuation through the adsorbate layer. However, Cu migration is still observed as an increased Cu:Ag ratio after CO₂ adsorption (**Figure 3c**). A chemistry driven surface reconstruction process similar to that induced by CO₂ adsorption alone is also observed when the surface is exposed to CO₂ in the presence of H₂O (**Figure 3b**). We found that Cu migration occurs on both Ag-lean and Ag-rich surfaces, showing as Cu:Ag ratio increment, but it is more obvious on the Ag-rich surface (**Figure 3c**).

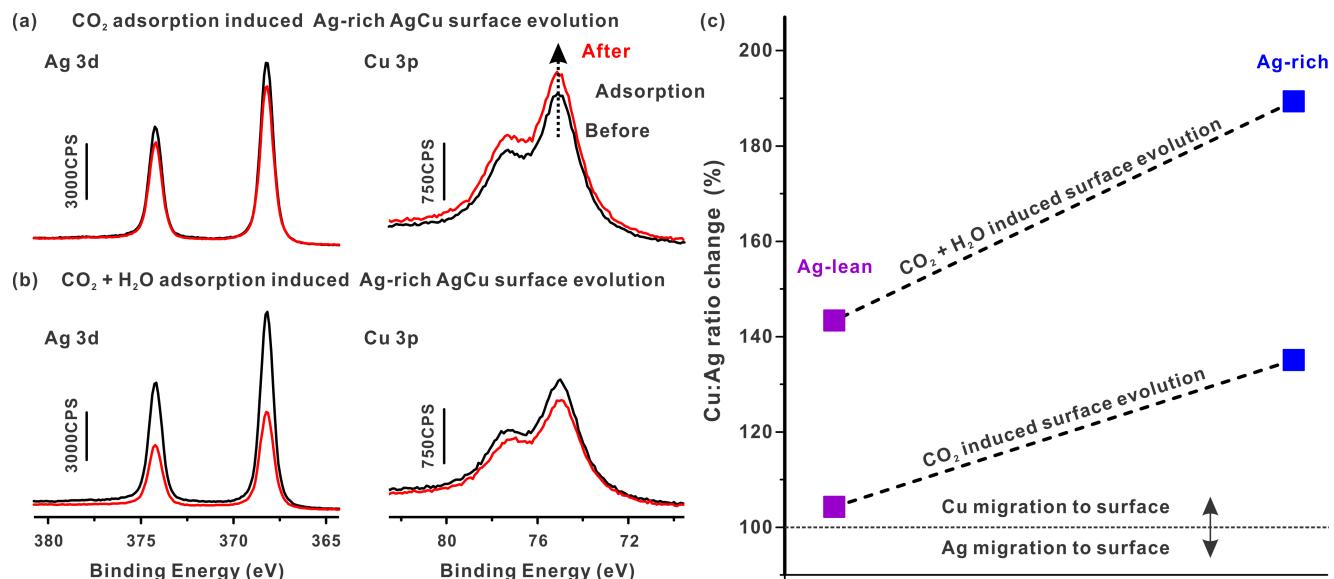

Figure 3. The changes of catalysts component distribution induced by the gas adsorption. The Ag 3d and Cu 3p intensity changes because of the CO₂ adsorption (**a**) alone and (**b**) in the presence of H₂O. (**c**) The Cu:Ag ratio changes for Ag-lean and Ag-rich surfaces induced by the gas adsorption. With CO₂ adsorption, the Ag 3d signals decreased to 93.3% and 87.2%, while the Cu 3p signals changed to 97.3% and 135.1%, respectively, for Ag-lean and Ag-rich AgCu surfaces. With CO₂ and H₂O co-adsorption, the Ag 3d signals decreased to 56.4% and 49.3%, while the Cu 3p signals decreased to 80.9% and 93.2%, respectively, for Ag-lean and Ag-rich AgCu surfaces. The catalyst signals did not show the same attenuation level after gas adsorption, indicating the surface reconstruction induced by the gas adsorption. The Cu:Ag ration change is higher than 100% for all the cases, proving the Cu migration to the surface induced by gas adsorption. The adsorption induced Cu migration is more obvious on the Ag-rich surface than on Ag-lean surface.

This surface reconstruction is correlated with the formation of surface O, which is probably formed by CO₂ or H₂O dissociation on Ag sites. The surface O induced surface reconstruction has been well established on Ag (111) and Cu (111) surfaces.⁴³⁻⁴⁴ Our previous works showed that the adsorption of CO₂ is not stable on Ag (111) surface with Ag vacancy induced by surface O,²⁴ and CO₂ is also not stable on the oxygen covered Cu (111) surface.²² Thus, we consider that CO₂ dissociates at the Ag site to form CO and surface O that further attracts subsurface or bulk Cu to initiate surface reconstruction. The surface O is observed as a ~529.8 eV peak in the O 1s spectra on both surfaces exposed to CO₂ (and H₂O), corresponding to the O_{ads} on Cu (**Figure S9**). Thus, the configuration of (O-Cu)-Ag formed with surface O adsorption. However, this configuration shows different properties with the previously extensively reported Cu-metal oxide system.^{25-26, 29-30} The Cu atoms interacting with O_{ads} would not provide sites for CO₂ adsorption.²² Instead, the Cu atoms interacting with Ag atoms can initiate the CO₂ adsorption (**Figure 1** and **Figure S6**). This configuration (Figure 1a,b) behaved like Ag-O_x-Cu interface, where the surface O and Cu tuned the CO₂ adsorption on the Ag site (**Figure 2a**). The Ag-rich surface has more Ag sites interacting with Cu compared with the Ag-lean surface, allowing more surface O formation to initiate Cu migration (**Figure 3c**), which also in turn changes the adsorbate-catalyst interactions. The surface reconstruction process shows a synergetic effect between Ag and Cu that tunes the CO₂ adsorption. We further investigated the CO₂ adsorption on the oxidized AgCu surface. The AgCu surface was heated in 30 mTorr O₂ at 450 K for 5mins. We found that Ag 3d intensity decreased significantly, while the Cu 3p intensity increased (**Figure S10**). Moreover, we observed an O 1s peak locating at 530.3 eV after AgCu treated in O₂, representing the formation the CuO_x (Cu₂O dominated). Thus, we concluded that heating AgCu in 30 mTorr O₂ at 450 K leads to the formation of a CuO_x layer on top of AgCu, denoting as CuO_xAg. CO₂ adsorption on this CuO_xAg surface leads to a peak appearing at around 289 eV, corresponding to the ionic carbonate, which is in line with previous study.²²

Our studies lead to new insights about CO₂ adsorption on the AgCu bimetallic surface. Unlike on pure metal surfaces, gas adsorption on the bimetallic surface depends on the energetics of chemistry driven surface reconstruction in addition to the surface adsorbate stability. The CO₂-AgCu interactions change as the surface evolves, showing tunability of CO₂ adsorption on AgCu. Surface reconstruction for bimetallic systems induced by gas adsorption is well-known⁴⁵⁻⁵⁰, but the atomic level detail have not been available. We find that the surface reconstruction induced by gas adsorption changes the underlying energetics of surface adsorbates. The synergetic effect between the Ag and Cu modifies the interactions between adsorbates and catalyst by changing the active surface sites and adsorption configurations. These results provide fresh insights into CO₂ adsorption and the initial steps of CO₂ activation on AgCu surfaces, showing surface reconstruction that is dramatically different from the pure Ag and Cu surfaces.

4. Conclusions

Our study emphasizes the power of combining advanced surface characterization techniques, APXPS, with QM predictions to provide a new level of atomistic understanding of how surface phenomena modify the fundamental underlying CO₂ adsorption and activation on bimetallic surface. We discovered how the CO₂ adsorption on AgCu bimetallic surface is tuned by the synergy between Ag and Cu. We find that the energetics of chemistry driven surface reconstruction can significantly modify the surface adsorbates properties, providing a new insight for manipulating the alloy surface to achieve selectivity and activity. These findings should stimulate new thinking about CO₂ reduction reactions on bimetallic surfaces, suggesting that the stabilization and activation of various adsorption configurations can be controlled through alloying different metals and suitable surface modifications.
